

# Using A2A with SWE-bench for Analyzing Agent Capability

Manish Muttreja  
manishmuttreja@gmail.com

## Abstract

SWE-bench has emerged as the de facto standard for evaluating language model agents on real-world software engineering tasks. While recent systems achieve 65%+ resolution on SWE-bench Verified, the benchmark suffers from three critical limitations: (1) data contamination—models may have memorized repositories and patches during pretraining; (2) patch-only scoring—evaluation ignores the engineering process; and (3) static test dependence—fixed test suites can be overfit. I present SWE-Bench-A2A, an evaluation framework and infrastructure for investigating these limitations through: retro-holdout mutations [6] to detect contamination, adversarial testing infrastructure, trajectory-based process scoring, and a reproduction-first gate. Cross-provider evaluation using semantic patch comparison (not execution-based pass/fail) with GPT-4o (20.7% avg semantic match on 100 tasks) and Claude model family—Sonnet 4.5 (27.7%), Opus 4.1 (18.8%), Haiku (18.5%)—demonstrates framework generality across 4 models and 2 providers. Important limitations: (1) experiments 5–6 describe methodology only—large-scale contamination/adversarial analysis is pending; (2) reported metrics are semantic similarity, not execution-based resolution; (3) the heuristic solver was used only in Experiment 1; all other experiments used LLM-only runs. I provide Dockerfiles and CI scaffolding for AgentBeats integration.

## 1 Introduction

The rapid advancement of large language models (LLMs) has enabled a new class of software engineering agents—systems that can understand codebases, diagnose bugs, and generate patches with minimal human intervention. Evaluating these agents requires benchmarks that capture the complexity of real-world software engineering while resisting the

pitfalls of static evaluation.

SWE-bench [1] represents a significant step forward, drawing from 2,294 real GitHub issues across 12 popular Python repositories. Unlike synthetic benchmarks, SWE-bench tasks require agents to navigate complex codebases, understand issue descriptions, and produce patches that pass repository test suites. This execution-based evaluation provides a strong signal of functional correctness.

However, as SWE-bench has become ubiquitous in agent evaluation, three fundamental limitations have emerged:

1. **Data Contamination:** The repositories in SWE-bench (Django, Flask, Scikit-learn, etc.) are among the most common in LLM training corpora. Models may have memorized not just the codebases but the specific patches that resolve benchmark issues.
2. **Patch-Only Scoring:** Current evaluation awards full credit for any patch that passes tests, ignoring whether the agent understood the problem. A model that guesses correctly receives the same score as one that systematically debugged the issue.
3. **Static Test Dependence:** Fixed test suites can be overfit through pattern matching without true understanding. Agents may learn to produce patches that pass specific tests while failing on equivalent formulations.

I present SWE-Bench-A2A, an evaluation framework that addresses these limitations through four key techniques:

- **Reproduction Gate:** Agents must first produce a failing test that reproduces the bug, demonstrating understanding before patching.
- **Process Scoring:** Beyond pass/fail, the framework captures full agent trajectories and com-

puts multi-dimensional scores for correctness, process quality, efficiency, and adaptation.

- **Anti-Memorization:** I apply retro-holdout mutations [6] to SWE-bench, transforming codebases with semantic-preserving renames. A fresh issue harvester provides never-before-seen tasks.
- **Dynamic Testing:** Beyond repository tests, the framework supports fuzz testing, mutation testing, and adversarial probes to detect overfitting.

The framework implements the Agent-to-Agent (A2A) protocol, enabling modular composition of assessors (Green Agents) and participants (Purple Agents). This design allows any solver to be evaluated without modification, promoting reproducibility and fair comparison.

## 2 Related Work

### 2.1 Code Generation Benchmarks

Early code benchmarks like HumanEval [2] and MBPP [3] evaluate function-level generation from docstrings. While useful for measuring basic coding ability, these synthetic tasks lack the complexity of real software engineering: multi-file reasoning, dependency management, and test integration.

### 2.2 Repository-Level Evaluation

SWE-bench [1] pioneered repository-level evaluation using real GitHub issues. The SWE-bench Verified subset (500 instances) provides human-validated instances with clearer specifications. The official leaderboard<sup>1</sup> tracks state-of-the-art systems, with mini-SWE-agent achieving 65% resolved and SWE-agent 1.0 as the open-source SOTA. However, these “% resolved” metrics may not fully capture agent capability due to contamination and overfitting concerns. Concurrent work like DevBench [4] extends to multi-language settings.

### 2.3 Contamination and Memorization

Data contamination in LLM benchmarks has been extensively documented [5]. For code benchmarks, the problem is acute: popular repositories appear repeatedly in training data. Techniques like canary

strings and holdout sets provide partial mitigation but cannot detect memorization of existing public data.

### 2.4 Process-Aware Evaluation

Traditional software engineering emphasizes process quality alongside outcomes. Test-driven development (TDD) requires understanding before implementation. The reproduction gate operationalizes this principle for agent evaluation.

## 3 Limitations of Current SWE-bench

### 3.1 Data Contamination

SWE-bench repositories are among the most-starred Python projects on GitHub. Analysis suggests substantial overlap with common training corpora:

- Django: 76k+ stars, extensive documentation
- Flask: 66k+ stars, widely referenced in tutorials
- Scikit-learn: 58k+ stars, standard ML library

Models trained on web-scale data have likely seen these codebases, their issues, and their patches. Performance on “unseen” tasks may reflect recall rather than reasoning.

### 3.2 Patch-Only Evaluation

Current scoring treats all passing patches equally:

$$\text{Score} = \mathbb{I}[\text{all tests pass}] \quad (1)$$

This binary metric ignores:

- Whether the agent understood the bug
- The quality of the debugging process
- Efficiency of the solution path
- Ability to handle ambiguity

### 3.3 Static Test Overfitting

Repository test suites, while valuable, have fixed specifications. Agents may learn patterns that satisfy specific tests without generalizing. A patch that passes `test_user_login` may fail on semantically equivalent `test_account_authentication`.

---

<sup>1</sup><https://www.swebench.com/>

## 4 SWE-Bench-A2A Design

### 4.1 A2A Protocol Architecture

The framework implements the Agent-to-Agent protocol with two actor types:

Green Agent (Assessor) Orchestrates evaluation: provisions environments, dispatches tasks, verifies solutions, computes scores.

Purple Agent (Solver) Attempts tasks: receives issue descriptions, explores codebases, generates patches.

Communication occurs via REST endpoints with standardized message formats:

```
# Task creation
POST /a2a/task
{
  "title": "Fix bug #1234",
  "description": "...",
  "resources": {"repo": "...", "commit": "..."}
}

# Artifact submission
POST /a2a/task/{id}/artifact
{
  "type": "patch_submission",
  "parts": [{"type": "file_diff", "content": "..."}]
}
```

This separation enables any solver to be evaluated without code changes, promoting fair comparison across systems.

### 4.2 Reproduction Gate

Before accepting patches, the framework requires agents to demonstrate bug understanding through reproduction:

This gate enforces test-driven development principles: understand the problem (red), then fix it (green).

### 4.3 Trajectory-Based Process Scoring

The framework captures complete agent trajectories and computes multi-dimensional scores:

$$\begin{aligned}
 S = & 0.35 s_{\text{correct}} + 0.20 s_{\text{process}} \\
 & + 0.15 s_{\text{efficiency}} + 0.15 s_{\text{collab}} \\
 & + 0.10 s_{\text{understand}} + 0.05 s_{\text{adapt}}
 \end{aligned} \tag{2}$$

---

### Algorithm 1 Reproduction Gate Protocol

---

Require: Issue description  $I$ , environment  $E$

- 1: Agent submits reproduction script  $R$
  - 2: Execute  $R$  in unpatched  $E$
  - 3: if  $R$  does not fail then
  - 4:   reject: "Reproduction must fail before patch"
  - 5: end if
  - 6: Agent submits patch  $P$
  - 7: Apply  $P$  to  $E$
  - 8: Run full test suite
  - 9: return verification result
- 

where the scoring dimensions are:

Category	Weight	Description
Correctness	0.35	Tests pass, patch applies
Process	0.20	Systematic exploration
Efficiency	0.15	Token/time usage
Collaboration	0.15	Information requests
Understanding	0.10	Reproduction quality
Adaptation	0.05	Response to feedback

Table 1: Scoring dimensions and weights

### 4.4 Anti-Memorization Strategies

#### 4.4.1 Retro-Holdout Mutations

Following the retro-holdout methodology introduced by Haimes et al. [6], I apply semantic-preserving mutations to detect contamination:

- Variable renaming: `data`  $\rightarrow$  `payload`
- Function renaming: `get_user`  $\rightarrow$  `fetch_account`
- Class renaming: `UserManager`  $\rightarrow$  `AccountHandler`
- Comment perturbation: Rephrase docstrings

Mutations are applied consistently across the codebase while preserving test behavior. This creates "parallel universes" where memorized patches no longer apply.

#### 4.4.2 Fresh Issue Harvesting

A harvester monitors GitHub for new issues in target repositories, providing tasks created after model training cutoffs. These "secret-in-time" instances provide contamination-free evaluation.

## 4.5 Dynamic Testing

Beyond repository tests, the framework provides hooks for (not enabled by default in reported runs):

Fuzz Testing Property-based tests with random inputs

Mutation Testing Assert patches handle code mutations

Adversarial Probes LLM-generated edge cases

## 5 Implementation

### 5.1 System Architecture

The implementation consists of several key components:

- **A2A Server:** FastAPI-based REST API implementing the A2A protocol with endpoints for task management, artifact submission, and health checks.
- **Environment Orchestrator:** Docker-based container management with JIT provisioning, repository cloning, and commit checkout.
- **Verification Engine:** Patch application, test execution with timeout handling, and flaky test detection.
- **Trajectory Capture:** Action logging with database persistence and streaming support.
- **LLM Solver:** Integration with OpenAI/Anthropic APIs for reproduction script and patch generation. The solver includes a three-tier fallback hierarchy: (1) real LLM API calls when API keys are configured, (2) heuristic patches for known benchmark instances (e.g., django-11099), and (3) mock responses when no API access is available. This design enables both production evaluation with frontier models and development testing without API costs.

### 5.2 Docker Images

I provide Dockerfiles for containerizing the Green and Purple agents. Image publishing (registry, tags, and access) is deployment-specific; the repository includes the artifacts needed to build and push images via CI for use with the AgentBeats evaluation platform.

## 6 Experiments

### 6.1 Setup

I ran seven experiments to validate the framework:

- Experiments 1–4: Establish baseline metrics using semantic patch comparison across 3–100 instances with GPT-4o.
- Experiments 5–6: Describe anti-contamination and adversarial testing methodology (infrastructure implemented, large-scale analysis pending).
- Experiment 7: Cross-provider evaluation with Claude model family (100 instances each).

Experiments 1–4 and 7 provide quantitative results; experiments 5–6 describe the methodology and infrastructure for future contamination/robustness analysis.

**Heuristic solver status:** The three-tier fallback hierarchy (LLM  $\rightarrow$  heuristic  $\rightarrow$  mock) was used only in Experiment 1 for integration testing. Experiments 2–4 and 7 used LLM-only runs with heuristics explicitly disabled. This is confirmed in the test scripts which set `allow_heuristics=False`.

**Reproduction Gate status:** The reproduction gate protocol (Algorithm 1) was not enforced in these experiments. All reported metrics are from direct patch generation without requiring a failing reproduction script first. Integrating mandatory reproduction enforcement is future work.

**Process Score status:** The composite Process Score  $S$  (Equation 2) is not computed in reported experiments. Experiments report semantic match (F1) only. Process scoring infrastructure exists but full trajectory analysis is not yet integrated into the evaluation pipeline.

### 6.2 Experiment 1: Integration smoke test (3 Django instances)

**Purpose:** ensure end-to-end plumbing (environment provisioning, A2A dispatch, patch apply, test execution) works under Docker.

- `django__django-11099:` UsernameValidator trailing newline (passed via heuristic baseline)
- `django__django-11133:` HttpResponse charset handling (LLM patch failed to apply)

- django\_\_django-11179: model\_to\_dict for unsaved model (LLM patch failed to apply)

Instance	Patch	Tests	Time	Source
django-11099	✓	3/3	74s	Heuristic
django-11133	×	0/0	73s	LLM
django-11179	×	0/0	71s	LLM
Total	33.3%	-	-	-

Table 2: Integration smoke test: confirms Docker + A2A pipeline; highlights solver fragility on diff formatting.

Important note: The 33.3% success rate is from a heuristic baseline, not the LLM solver. The LLM-only success rate was 0% (0/2 tasks where LLM was used). This confirms infrastructure correctness while highlighting LLM solver fragility on diff formatting.

### 6.3 Experiment 2: GPT-4o benchmark (20 instances)

Purpose: measure solver quality with a stronger model on a broader slice. Evaluation uses semantic patch comparison (code-change overlap via F1 score between generated and expected patch tokens) rather than execution-based pass/fail.

Important note on metrics: The “F1 Score” and “Semantic Match” reported in this paper measure textual similarity between generated patches and expected patches—not the composite Process Score  $S$  defined in Section 4.3, and not execution-based test pass/fail. A high semantic match indicates the patch is textually similar to the expected solution but does not guarantee functional correctness (a single syntax error could prevent execution). This limitation applies to all experiments in this paper.

Metric	Value
Tasks Tested	20
Perfect Solutions (F1=100%)	15% (3/20)
High Match (>50%)	30% (6/20)
Average F1 Score	32.8%

Table 3: GPT-4o aggregate metrics on 20 SWE-bench Verified instances.

Representative outcomes (semantic match shown):

- 100% sklearn\_\_sklearn-14141: add joblib to show\_versions deps (perfect semantic match).

- 100% django\_\_django-13406: queryset handling fix (perfect).
- 93% pallets\_\_flask-5014: blueprint registration fix (near-perfect).
- 80% sympy\_\_sympy-23534: symbol handling (strong partial).
- 0–50% Several SymPy/Django tasks: correct file localization but partial or divergent semantics.

Key findings:

1. File localization remains perfect: 100% correct files on 20/20 tasks, confirming strong navigation.
2. Semantic quality is mixed: 25% perfect, 35% high-match; average semantic match rises to 43.2% on the larger slice.
3. Repository difficulty: Django and Flask skew higher (multiple 100%/93% cases); SymPy and some Django tests remain challenging with 0–50% matches.
4. Cost efficiency holds: \$0.006 per task with frontier model API calls.

Context vs. public baselines: Public SWE-bench Verified baselines for earlier GPT-4-era systems typically report low double-digit pass@1. The semantic-match view shows GPT-4o producing functionally close patches on a meaningful fraction of tasks even when strict exact-match metrics would undercount success. This highlights the importance of reporting both exact and semantic measures when comparing against public results.

### 6.4 Experiment 3: GPT-4o variance analysis (10 instances)

Purpose: assess run-to-run variance on identical tasks. GPT-4o processed the same 10 SWE-bench Verified instances in multiple independent runs.

Metric	Run 1	Run 2	Run 3	Run 4
Tasks	10	10	10	10
Avg F1 Score	17.8%	10.4%	17.2%	7.0%

Table 4: GPT-4o variance across 4 runs on 10 identical tasks.

Key findings:

1. High variance at small scale: F1 scores range from 7.0% to 17.8% across runs, demonstrating the need for multiple runs or larger samples.
2. sklearn-14141 consistently solved: This instance achieved 100% F1 in multiple runs, suggesting model familiarity with this specific task.
3. SymPy remains challenging: Tasks from SymPy repository consistently scored 0% across all runs.

#### 6.5 Experiment 4: Large-scale benchmark (100 instances)

Purpose: validate findings at scale with statistically significant sample size. GPT-4o processed 100 SWE-bench Verified instances in two independent runs.

Metric	Run 1	Run 2
Tasks Completed	100/100	100/100
High Match ( $\geq 50\%$ )	17	14
Avg F1 Score	20.7%	19.3%

Table 5: GPT-4o 100-task benchmark: two independent runs show consistent performance.

Key findings at scale:

1. Consistent performance: Two independent runs show similar F1 scores (20.7% vs 19.3%), indicating stable model behavior.
2. High reliability: 100% task completion in both runs shows production-ready robustness.
3. Scale improves assessment: 100-task runs provide more statistically reliable metrics than smaller samples.

#### 6.6 Experiment 5: Anti-Contamination Framework (Methodology)

Purpose: The framework implements retro-holdout mutations to detect contamination. While the infrastructure is complete, full evaluation at scale is pending.

Methodology: The anti-contamination pipeline applies semantic-preserving transformations (variable/function/class renaming, docstring rephrasing) to create “mutated” versions of SWE-bench instances. Performance drops between original and mutated versions indicate memorization.

Preliminary observation: GPT-4o achieved 100% F1 on sklearn-14141 consistently across multiple runs, suggesting potential memorization of this specific task. The anti-contamination infrastructure is ready to test this hypothesis by comparing performance on original vs. mutated instances.

Status: The retro-holdout infrastructure is implemented and available in the repository. Comprehensive contamination analysis across 100+ instances is planned for future work.

#### 6.7 Experiment 6: Adversarial Testing Framework (Methodology)

Purpose: The framework implements adversarial testing to quantify patch robustness beyond test-pass metrics.

Methodology: The adversarial evaluator includes three components:

- Fuzz Testing: Property-based tests with random inputs to verify defensive coding
- Adversarial Edge Cases: LLM-generated edge cases (null inputs, boundary conditions, malformed data)
- Mutation Testing: Code mutations (operator swaps, boundary changes) to test patch resilience

Hypothesis: Patches that pass repository tests may still be fragile to real-world usage variations. Standard “% resolved” metrics may overstate robustness.

Status: The adversarial testing infrastructure is implemented and available in the repository (src/adversarial/). Comprehensive robustness analysis is planned for future work.

#### 6.8 Experiment 7: Claude Model Family Benchmark (100 instances)

Purpose: Evaluate Anthropic’s Claude model family on SWE-bench to compare against OpenAI models and validate framework generality across model providers.

Variance caveat: Experiment 3 showed GPT-4o variance of 7.0%–17.8% across runs on identical tasks. This Claude evaluation represents a single run per model; cross-model comparisons should be interpreted cautiously given this variance.

Key findings:

Metric	Claude 3 Haiku	Opus 4.1	Sonnet 4.5
Tasks Completed	98/100	100/100	100/100
Avg Semantic Match	18.5%	18.8%	27.7%
High Match ( $\geq 70\%$ )	1	3	8
Perfect Match ( $\geq 95\%$ )	0	0	0
Total Tokens	92,810	114,760	103,511

Table 6: Claude model family comparison (100 instances each). Sonnet 4.5 leads.

Model	Tasks	Avg Match	High ( $\geq 70\%$ )
Claude Sonnet 4.5	100/100	27.7%	8
GPT-4o	100/100	20.7%	13
Claude Opus 4.1	100/100	18.8%	3
Claude 3 Haiku	98/100	18.5%	1

Table 7: Cross-provider model rankings on SWE-bench (100 instances).

1. Claude Sonnet 4.5 leads on avg match: 27.7% average F1, outperforming GPT-4o (20.7%) and other Claude models.
2. GPT-4o leads on high-quality solutions: 13 solutions with  $\geq 70\%$  F1, vs 8 for Sonnet 4.5.
3. Opus 4.1 comparable to Haiku: Both achieve  $\sim 18.5\%$  avg match, significantly below Sonnet 4.5.
4. Framework generality validated: The A2A framework successfully evaluates 4 different models across 2 providers without modification.

Notable high-match results for Claude Sonnet 4.5:

- Best: sklearn-12585 (91.3%), django-11163 (91.7%), xarray-4629 (85.5%)
- Strong: django-13670 (65.2%), pytest-7205 (66.9%), django-11451 (91.3%)

This cross-provider evaluation demonstrates the A2A framework’s generality—it can evaluate any LLM backend without modification.

## 6.9 Trajectory Analysis

For successful cases, the captured trajectory shows:

```
1. scenario_select -> instance_id
2. provision_environment -> [container_id]
3. dispatch_task -> [purple_task_id]
4. receive_artifact -> reproduction_script
```

5. receive\_artifact -> patch\_submission  
6. verification -> passed (tests)  
This visibility enables debugging agent behavior and computing process scores.

## 7 Impact of Novel Techniques

Important clarification: This section describes infrastructure and hypotheses, not proven results. The novel techniques are implemented but not yet validated through experiments.

7.1 Contamination Detection via Retro-Holdout

The retro-holdout methodology [6] applies semantic-preserving mutations to detect memorization.

- Observation: GPT-4o achieved 100% F1 on sklearn-14141 consistently across multiple runs.
- Hypothesis: This consistency may indicate memorization. If true, performance should drop on mutated versions.
- Status: The experiment to test this hypothesis has not been executed. Infrastructure is ready; results are pending.

### 7.2 Robustness via Adversarial Testing

The adversarial framework provides infrastructure for fuzz inputs, edge cases, and code mutations.

- Hypothesis: Patches passing repository tests may be fragile to real-world variations.
- Status: No adversarial experiments were executed. Infrastructure exists in src/adversarial/; validation is future work.

### 7.3 Process Quality via Trajectory Scoring

The multi-dimensional Process Score  $S$  (Equation 2) captures process quality beyond pass/fail.

- Components: Correctness, process, efficiency, collaboration, understanding, adaptation
- Status: Process scoring is not computed in reported experiments. Only semantic match (F1) is reported. Whether process scoring differentiates systematic debugging from guessing remains unvalidated.

## 8 Evaluation Slices

I propose four evaluation slices for comprehensive assessment:

Verified Standard SWE-bench Verified instances

Mutated Retro-holdout transformed versions

Fresh Newly harvested issues (<24h old)

Adversarial Instances with fuzz/mutation testing

Reporting across slices reveals contamination sensitivity and robustness.

## 9 Limitations and Future Work

### 9.1 Current Limitations

- Semantic similarity  $\neq$  functional correctness: All experiments use semantic patch comparison (F1 score between patch tokens), not execution-based test pass/fail. A patch with 95% semantic match could still fail due to syntax errors. This metric may over-optimistically assess non-functional code. Future work should include execution verification.
- Process Score not computed: The composite score  $S$  (Equation 2) capturing process quality is defined but not computed in reported experiments. Only semantic match is reported.
- Reproduction Gate not enforced: The reproduction-first protocol (Algorithm 1) was not mandatory in experiments. No funnel analysis (reproduction failures vs. patching failures) is available.
- Single-run comparisons: Experiment 3 shows 7.0%–17.8% variance across runs. Experiment 7 (Claude) is single-run, making cross-model rankings statistically fragile.
- Retro-holdout/adversarial not executed: Experiments 5–6 describe methodology only. The claim that this framework “solves” contamination is currently infrastructure, not proven results.
- Python only: Current implementation focuses on Python repositories.
- Heuristic fallback risk: While disabled for Experiments 2–7, the heuristic solver’s presence in the codebase poses a validity risk if accidentally enabled.

### 9.2 Future Directions

1. Integrate additional frontier models (Gemini 2.0, Llama 3) for Purple agent comparison
2. Complete retro-holdout pipeline with semantic equivalence verification
3. Implement default fuzz command packs for common frameworks
4. Extend to multi-language evaluation (TypeScript, Rust)
5. Add visual/multimodal signals for UI-related bugs
6. Scale evaluation to full SWE-bench Verified (500+ instances)

## 10 Conclusion

SWE-Bench-A2A provides evaluation infrastructure (not proven results) for investigating three critical gaps in current SWE-bench evaluation:

1. Contamination Detection (Retro-Holdout): Infrastructure for semantic-preserving mutations is implemented. GPT-4o’s consistent 100% F1 on sklearn-14141 suggests potential memorization, but the retro-holdout experiment has not been executed. The contamination hypothesis remains unproven.
2. Robustness Testing (Adversarial): Fuzz testing, adversarial edge cases, and mutation testing infrastructure exists in src/adversarial/. No adversarial experiments were executed. The hypothesis that “% resolved” overstates robustness is untested.
3. Process Scoring (Trajectory): The multi-dimensional scoring formula (Equation 2) is defined, but not computed in reported experiments. Only semantic match is reported. Process scoring remains future work.

What this paper actually demonstrates:

- Framework generality: The A2A framework evaluates 4 models across 2 providers using semantic patch comparison

- Semantic match baseline: GPT-4o achieves 20.7% avg semantic match; Claude Sonnet 4.5 achieves 27.7%
- Infrastructure availability: Dockerfiles, CI scaffolding, and code for retro-holdout/adversarial testing

What remains unproven:

- Whether retro-holdout actually degrades model performance (contamination hypothesis)
- Whether adversarial testing exposes patch fragility (robustness hypothesis)
- Whether process scoring differentiates systematic debugging from guessing
- Execution-based pass/fail verification (all reported metrics are semantic similarity)

I recommend future work execute the retro-holdout experiment and report execution-based metrics alongside semantic match.

## Acknowledgments

I thank the SWE-bench team for their foundational work and the AgentBeats community for evaluation infrastructure.

## A A2A Protocol Specification

### A.1 Agent Card Format

```

1 {
2   "name": "SWE-bench Green Agent",
3   "version": "1.0.0",
4   "agent_id": "uuid",
5   "capabilities": ["swebench_evaluation"],
6   "endpoints": {
7     "task": "/a2a/task",
8     "health": "/health"
9   }
10 }
```

### A.2 Artifact Types

- reproduction\_script: CODE artifact with failing test
- patch\_submission: FILE\_DIFF artifact with unified diff
- assessment\_result: JSON artifact with verification results

## B Scoring Formula Details

### B.1 Correctness Score

$$s_{\text{correct}} = 0.6 \cdot \mathbb{I}[\text{pass}] + 0.3 \cdot \frac{\text{tests\_passed}}{\text{total\_tests}} + 0.1 \cdot \mathbb{I}[\text{patch\_applied}] \quad (3)$$

### B.2 Process Score

$$s_{\text{process}} = 0.4 \cdot s_{\text{exploration}} + 0.3 \cdot s_{\text{reasoning}} + 0.3 \cdot s_{\text{reproduction}} \quad (4)$$

### B.3 Efficiency Score

$$s_{\text{efficiency}} = 0.4 \cdot \frac{T_{\text{budget}} - T_{\text{used}}}{T_{\text{budget}}} + 0.4 \cdot \frac{N_{\text{budget}} - N_{\text{tokens}}}{N_{\text{budget}}} + 0.2 \cdot \frac{1}{1 + \text{attempts}} \quad (5)$$
